Gradient syllable weight and weight universals in quantitative metrics*

Kevin M. Ryan
Harvard University

Homeric Greek, Kalevala Finnish, Old Norse and Middle Tamil are all languages in which weight is claimed to be exclusively binary in the poetic metrics. As I demonstrate through corpus studies of these traditions, the poets were sensitive to additional grades of weight, such that finely articulated continua of syllable weight can be inferred from distributional asymmetries in the metres. Across all four languages, the scales are strongly correlated (for example, in each, $C_0V < C_0VC < C_0VV < C_0VVC$). These language-internal scales reflect the cross-linguistic typology of categorical weight criteria, providing new evidence for weight universals. A metrical grammar is proposed in a maximum entropy constraint framework in which categorical and scalar/gradient constraints interact to generate the weight-mapping typology.

In quantitative metre, rhythm is instantiated through mapping conventions regulating the distribution of syllable weight in verse constituents (e.g. Halle 1970, Halle & Keyser 1971, Hayes 1988). Most typically, a distinction between heavy and light syllables is observed, such that certain contexts permit one or the other, but not both. Through corpus studies of four metrical traditions, I demonstrate that the poets' manipulation of phonological material in every one is influenced by sensitivity to additional weight contrasts. These contrasts emerge not as categorical restrictions, but as significant preferences, even while controlling for possible lexical and contextual confounds using mixed effects models.

In particular, I examine the Homeric Greek hexameter, the Finnish Kalevala metre, the Old Norse *dróttkvætt* and the metre(s) of Kamba̱n's Middle Tamil epic. Each corpus contains between 10,000 and 50,000 metrically parsed lines. In each metre, asymmetries in the metrical

distributions of syllable types permit the derivation of a detailed interval scale of weight. For example, the same skeletal hierarchy is observed across languages: $C_0V < C_0VC < C_0VV < C_0VVC$ (every link significant at $p < 0.01$ in every language).[1] Pursued further, this method reveals some of the most articulated syllable-weight scales documented for individual languages, all in metres in which weight is usually assumed to be exclusively binary. That these scales reflect weight is supported by typological parallels with other weight-sensitive systems, including stress. First, the structure of the rhyme takes precedence over that of the onset. Second, more structure (e.g. timing slots) correlates with greater weight. Third, even when complexity is held constant, greater sonority is associated with (if anything) greater weight (e.g. C_0V[obstruent] $< C_0V$[sonorant]; though see §4.3 for a caveat concerning the lightness of rhotic-final syllables in Tamil). As another example, among stress systems distinguishing the weights of C_0VC and C_0VV, the former is almost always the lighter; $C_0VC < C_0VV$ likewise holds of every metre examined here. Finally, if one defines a heavy syllable in metre as one that is required/preferred in strong metrical positions (or avoided in weak ones), it is sensible to speak of syllables that are progressively more favoured in strong over weak positions (all else being equal) as being progressively heavier.

A generative analysis is proposed in a maximum entropy constraint framework in which gradient/scalar constraints interact with their categorical counterparts to generate the weight-mapping typology. This typology includes quantity-sensitive systems exhibiting incomplete categorisation, i.e. some polarisation towards heavy and light categories (beyond what a purely phonetic model would imply), but with gradient sensitivity to the phonetic interface of weight continuing to leak through within categories.

In sum, although light (C_0V) *vs.* heavy is a prominent weight distinction in all four traditions, rising to the level of categoricality in at least some of them, I show that speakers of these languages were sensitive to various additional contrasts in syllable weight as factors influencing their choices in quantitative versification, a highly conventionalised language game in which syllable weight is manipulated to effect rhythm. Individual languages are like microcosms of the cross-linguistic typology in the gradient realm, in that weight factors that are ignored for categorisation emerge as statistical preferences following the same principles and universals as their categorical counterparts in other languages. These findings are significant for the phonology of weight, for metrical grammar and for modelling the interaction of categoricity and gradience in the treatment of scalar phenomena.

---

[1] The following abbreviations for segment classes are employed: C (consonants), V (short vowels), V: (long vowels), VV (long vowels and diphthongs), T (obstruents), N (nasals), L (laterals), R (rhotics) and J (glides). '<' denotes 'is lighter than'.
Figure 1
Directed graph for the Greek hexameter (H = heavy, L = light).
Node size is proportional to frequency.

1 The Ancient Greek hexameter

1.1 Metrical and corpus preliminaries

The Ancient Greek hexameter, as employed by poets such as Homer and Hesiod, is schematised in (1) (Maas 1962, Raven 1962, Halle 1970, West 1982, Prince 1989).[2] Each line comprises six METRA (metrical feet), as numbered along the top of the figure. A syllable is light (notated ˘) if it is C_0V; otherwise it is heavy (–). Each non-final metron contains a heavy followed by either another heavy or pair of lights. These two halves of the metron are often referred to as the LONGUM (L; obligatory –) and BICEPS (B; optional ˘ ˘ or –) respectively (West 1982).[3] The final metron contains a heavy followed by a single syllable of any weight.

(1) *Hexameter template*

1 & & 2 & & 3 & & 4 & & 5 & & 6 & \\
\text{L} & \text{B} & \text{L} & \text{B} & \text{L} & \text{B} & \text{L} & \text{B} & \text{L} & \text{B} & \text{L} & \\
- & \left\{ \begin{matrix} - \\ \smile\smile \end{matrix} \right\} & - & \left\{ \begin{matrix} - \\ \smile\smile \end{matrix} \right\} & - & \left\{ \begin{matrix} - \\ \smile\smile \end{matrix} \right\} & - & \left\{ \begin{matrix} - \\ \smile\smile \end{matrix} \right\} & - & \left\{ \begin{matrix} - \\ \smile\smile \end{matrix} \right\} & - & \left\{ \begin{matrix} - \\ \smile \end{matrix} \right\}
\end{array}
$$

Although the biceps always exhibits an option between – and ˘ ˘, the latter option is increasingly favoured later in the line, to the extent that the fifth (final) biceps is filled by a pair of lights over 95 % of the time. To illustrate this preference, the template can be depicted as a weighted directed graph, as in Fig. 1, in which the size of each node is proportional to its likelihood of traversal (the small nodes along the top all being 'H').[4]

The Ancient Greek corpus employed here consists of 24,677 parsed hexameters extracted from Homer's epics, the *Iliad* and the *Odyssey* (ca 750 BCE), as available online at the Thesaurus Linguae Graecae.[5] This corpus, prepared in collaboration with Dieter Gunkel, contains only lines that scan according to the template in (1). A Perl (Wall 2010) program

---

[2] This template addresses only weight, ignoring other features of the metre, including the caesura, which falls after the third longum, the first light of the third biceps or (rarely) the fourth longum.

[3] The terms *arsis* 'raising' and *thesis* 'lowering' are also employed for the two halves of the metron. However, these terms have been applied inconsistently, and I follow Maas (1962: 6) in avoiding them.

[4] These illustrations ignore sporadic exceptions, such as lights in line-initial position.

[5] http://www.tlg.uci.edu (accessed April 2009).

was used to automatically syllabify lines (according to standard rules; see Probert 2010: 100–101)[6] and assign syllables to metrical positions.[7] A point of ambiguity in syllabification concerns intervocalic clusters of a stop + liquid or nasal, which can be either heterosyllabic (VC.CV) or, less commonly, compressed into an onset (V.CCV) (see Steriade 1982: 186–208 for details). The parser first attempts to scan the line without compression; that failing, it attempts to compress every combination of eligible clusters (if any) until it finds a scansion or exhausts its options. If no parse is found (due to additional complications), the line is excluded from the present corpus, reducing the size of the corpus by 11% (from 27,758 original lines to the present 24,677 parsed lines).

1.2 Metrical sensitivity to intra-heavy weight

The hexameter templates in (1) and Fig. 1 imply that the metre regulates only binary weight, i.e. heavies and lights. Nevertheless, as some classicists have observed (see below), the poets appear to avoid placing the lightest types of heavies in the biceps (second half of the metron), while no comparable avoidance is observed in the longum (first half of the metron), suggesting that weight-sensitivity is more fine-grained. In the remainder of this section, I support this conclusion, while controlling for possible confounds, and further argue that the poets' choices reveal sensitivity to a continuum of weight within the heavies.

The biceps is sometimes claimed to be a longer position than the longum, such that the poets prefer to fill it with heavier phonological material (e.g. West 1970: 186, 1982: 39, 1987: 7, 22; cf. Maas 1962: §51, Irigoin 1965, Allen 1973, Devine & Stephens 1976, 1977, 1994, McLennan 1978). West makes this claim perhaps most explicit, stating in his textbooks that 'the biceps, being of greater duration [than the longum; KR], requires more stuffing' (West 1982: 39, 1987: 22). West's evidence for this discrepancy includes the overrepresentation of certain types of heavies in longa relative to bicipitia, including C_0V: in which V: is the result of lengthening a usually short vowel, C_0V: in which V: is prevocalic (i.e. stands in hiatus) and $C_0VC.CV$ in which C.C is a stop–liquid sequence (1970: 186ff). These types have in common that they are all on the lighter side of heavies; some, in fact, could actually scan as light if deployed in a light metrical position. For example, a short vowel followed by a stop–liquid interlude can scan either as heavy (VC.CV) or as light (V.CCV) (see §1.1). The consistent skews of these lighter types towards

---

[6] Summarising this algorithm for word-internal contexts, $V(C)V \rightarrow V.(C)V$; $VCCV \rightarrow VC.CV$ (though stop + liquid or nasal clusters are variable; see the text); $VC_{n \geq 3}V \rightarrow VC_{n-1}.CV$ (unless the interlude ends with a stop plus liquid or voiceless stop plus nasal, in which case it is divided $C_{n-2}.CC$).

[7] Moreover, in preparing the corpus, the orthographically ambiguous vowels α, ι and υ were annotated for length, drawing on a combination of automated and manual heuristics (see Ryan 2011: 41, 47 for details).

the longum suggests that the longum is lighter as a metrical position than the biceps. Indeed, even in the 1st century BCE, Dionysius of Halicarnassus (*De Compositione Verborum* §17 (Aujac & Lebel 1981); see Allen 1973: 255, West 1982: 18) cited contemporary rhythmicians as holding that the biceps was of longer duration than the longum. This view is corroborated and extended here.

Consider first C_0VC *vs.* C_0VV. Both types are categorically heavy, such that either may fill a longum or a biceps. For example, (2) contains two lines from the *Iliad*, with the second biceps boxed. The first contains C_0VC in this position, the second C_0VV. (The two syllables also occupy the same position of the word, being the medials of heavy–heavy–heavy trisyllables.)

(2) *Illustrations of biceps* $C_0\mathbf{V}C$ vs. C_0VV *from the* Iliad

  ‒ ˘ ˘]₁ ‒ ⎡‒⎤]₂ ‒ • ˘ ˘]₃ ‒ ˘ ˘]₄ ‒ ˘ ˘]₅ ‒ ‒]₆

Nevertheless, VV rhymes are significantly skewed towards bicipitia (relative to VC rhymes). In the Homeric corpus, the ratio of VV to VC is 66% greater in bicipitia than it is in longa ($p < 0.0001$), as detailed in Table I. Cross-linguistically, if a language distinguishes between the weights of VC and VV rhymes, it is virtually always the latter that is the heavier (Gordon 2006). These data therefore tentatively support the biceps as being heavier than the longum, though certain confounds are yet to be addressed.

	VV rhyme	VC rhyme	VV:VC ratio
longum	75,931	58,862	1·290
biceps	19,143	8,946	2·140

Table I
VV:VC ratios in longa *vs.* bicipitia in Homer.

In particular, while it is possible that the hexameter template is richer than binary, as West (1970, 1982, 1987) assumes, it is also possible that the different distributions of VC and VV reflect factors unrelated to syllable weight (Devine & Stephens 1976). First, VV and VC are not identically distributed in words, and different positions of the word might be treated differently by the metre, or subject to different degrees of

reduction/fortition (Devine & Stephens 1994 : 74). As hypothetical examples, perhaps word-initial heavies are treated as heavier than word-medial heavies by virtue of, say, initial strengthening (Keating *et al*. 2003) or privilege (Beckman 1998), or perhaps word-final heavies are treated as heavier than word-medial heavies due to final lengthening (Lunden 2006). Thus, VC might appear to be lighter than VV not because of its intrinsic weight as a syllable, but because it is more likely to occupy reduced positions in words or feet. I am not claiming that the metre is necessarily sensitive to these factors, merely that they are logically possible confounds for which one should control. Second, word shapes are distributed unevenly in metre. For example, any heavy preceding a light can only occupy a longum. The initial syllable of a heavy–light disyllable, for instance, is almost four times as likely to be VC as it is to be VV. This sort of discrepancy might explain the higher incidence of VC in longa without any recourse to weight. In sum, even ignoring intrinsic syllable weight, VC might be skewed towards longa due to the way it is distributed within words and the way words are distributed in the line.

One means of controlling for these confounds is to hold word shape and position in the word constant. Table II is a retabulation of Table I, counting only VC and VV rhymes that are initial in heavy–heavy disyllables. The conclusion is confirmed : even while holding word context constant, the proportion of VV rhymes is significantly greater in bicipitia ($p < 0.0001$).

	VV rhyme	VC rhyme	VV : VC ratio
longum	6,810	3,999	1·703
biceps	3,829	1,513	2·531

Table II
VV : VC ratios in # __ H# context only.

This approach, while simple, has two shortcomings. First, it drastically reduces the quantity of data brought to bear on the question, ignoring in this case over 90 % of heavy syllables in the corpus. For less frequent, more specific or more distributionally constrained syllable types, significant trends in the corpus as a whole might be lost on this kind of test. Second, it is unclear from such a test to what extent the same result holds across other positions of the word and other word shapes.

1.3 Controlling for word context with a mixed effects model

These shortcomings can be addressed by scaling up to a statistical approach that takes all the corpus data into account, while still controlling for word shape. One such approach is to enter word context as a random

effect in a mixed effects regression model.[8] Logistic regression assesses the contributions of factors in predicting a binary outcome, in this case, whether a given heavy is placed in a biceps (coded 1) or longum (coded 0). Two conditions are employed in this case to predict this outcome, namely, whether the heavy in question has a VC or VV rhyme (syllables with other rhymes are put aside here). Additionally, each syllable is coded for its WORD CONTEXT, i.e. the weight template of its word with its position 'X-ed out' (e.g. LXH for the medial of a light-initial and heavy-final trisyllable). Word context is included in the model as a random effect, as it has a very large (in principle infinite) number of levels, of which the hexameter corpus is a sample, if a large one (note that some word shapes, e.g. ‾ ˘ ‾, are unmetrifiable as such in the hexameter). Each word context is effectively assigned a baseline biceps-likelihood and variance, correcting for the possible positional confounds discussed above without sacrificing generality.[9]

Table III is a simple regression table. VC is treated as the baseline (intercept), while VV is coded as a (binary) factor. The crucial aspect of this table is that, even while the model corrects for word context, VV has a significant ($p < 0.05$) positive (0·34) coefficient, meaning it is significantly more skewed towards bicipitia than the intercept condition, VC.[10]

| rhyme	coefficient	standard error	z-value	p-value
intercept (i.e. VC)	−14·3833	2·3965	−6·00	< 0·00001
VV	0·3444	0·0214	16·07	< 0·00001

Table III
Logistic model predicting position from rhyme type.

[8] An alternative approach is a prose or nonsense comparison model, in which expected distributions under the null hypothesis are computed from prose samples (Tarlinskaja & Teterina 1974, Tarlinskaja 1976, Biggs 1996, Hayes & Moore-Cantwell 2011) or from randomly constructed lines (Ryan 2011: 55, Gunkel & Ryan, forthcoming). Ryan (2011) demonstrates that the same intra-heavy hierarchy derived in this section using regression is also derived using a Monte Carlo nonsense comparison method.

[9] On the justification and implementation of mixed effects regression models in linguistics (and advantages over older approaches such as ANOVAs), see Baayen (2004, 2008: §7), Baayen *et al.* (2008), Jaeger (2008), Quené & van den Bergh (2008) and Levy (2010). The models in this article are fit by maximum likelihood using *lmer*, part of the *lme4* package (Bates & Maechler 2009) for R (R Development Core Team 2009).

[10] The other reported numbers are standard. The standard error is the estimated standard deviation of each coefficient; the z- (or t-) value is the coefficient divided by the standard error; and the p-value is the probability of the z- (or t-) value being at least as great under the null hypothesis that the factor is inert.
Figure 2
Intercepts of the 20 most frequent word contexts (for X = heavy) in Homer.
Bar height indicates skew towards bicipitia (in logit units; see text).
The frequency of each context is given at the top of its bar.

The random effects for word context ($n = 114$) are not shown in Table III. Intercepts for the 20 most frequent word contexts in Homer are depicted as a bar chart in Fig. 2 (as in Levy 2010). The y-axis is the likelihood (in logit units) that X in each word context occupies a biceps (considering only words in which X is heavy), ranging from $-0 \cdot 87$ (for XL) to $24 \cdot 50$ (for XHL). In the leftmost thirteen word contexts, X is adjacent to a light, entailing that X occupy a longum; these intercepts are therefore uniformly low. The next six word contexts have intermediate intercepts, since X in these contexts can occupy either a longum or a biceps. Finally, in XHL, the rightmost context, X can only occupy a biceps, hence the high intercept. Word contexts are accompanied by their frequencies.

The model generates specific predictions as follows. Consider a VC rhyme in the word context XH, whose intercept is $13 \cdot 92$. The sum of the general and word context intercepts ($-14 \cdot 38 + 13 \cdot 92 = -0 \cdot 46$) is plugged into the logistic function, $1/(1 + e^{-x})$ (where $e \approx 2 \cdot 7183$), in this case giving $0 \cdot 387$, or a 39 % chance that VC in XH is placed in a biceps as opposed to longum. For VV in the same context, the sum also includes the relevant coefficient, giving a biceps likelihood of 47 %.

1.4 A more articulated hierarchy of intra-heavy weight

In §1.3, heavies were divided into two types, namely, VC *vs*. VV rhymes, putting aside heavies falling into neither class. I now further subdivide the

heavies, showing that the poets were sensitive to additional grades of weight within the heavies.[11]

First, VC is split into two groups, namely, V[obstruent] and V[sonorant]. Cross-linguistically, the latter is typically the heavier if a distinction is made, as in, for instance, Kwakw'ala (Boas 1947, Zec 1995) and Lamang (Wolff 1983, Gordon 2002). More generally, sonority is claimed to positively correlate with weight (Zec 1988, 1995, 2003, Morén 1999, de Lacy 2002, 2004, Gordon 2006). I also add to the model the level VVC. If the weights of VV and VVC are distinguished, typologically, the latter is expected to be the heavier, as in Pulaar (Niang 1995). More generally, more structure is expected to correlate with (if anything) greater weight (Hyman 1985, Gordon 2002). In sum, four intra-heavy levels are now considered: V[obstruent], V[sonorant], VV and VVC.

Table IV is the regression table. As in Table III, the model is logistic (binary outcome for placement in biceps), and word context is a random effect (not shown). Each rhyme type is entered as a factor, leaving out V[obstruent] as the intercept. Though one might think of rhyme type as being a single factor with different rhymes being conditions or levels of that factor, in this case each type is treated by the model as a (binary or Boolean) factor, so that the differences between types can be gauged. Factors here are forward-difference coded, meaning that each coefficient and p-value is interpreted not with respect to the general intercept (as with so-called dummy coding) but with respect to the preceding factor in the table (Venables & Ripley 2002).[12] The comparandum column makes this coding scheme explicit. The following hierarchy is observed: V[obstruent] < V[sonorant] < VV < VVC (every link p < 0·0001), mirroring the typologically inferred hierarchy for weight.

rhyme	comparandum	coefficient	standard error	z-value	p-value
intercept	i.e. V[obs]	−12·0876	1·9746	−6·12	< 0·00001
V[son]	*vs.* V[obs]	0·2726	0·0342	7·97	< 0·00001
VV	*vs.* V[son]	0·2266	0·0261	8·67	< 0·00001
VVC	*vs.* VV	0·2119	0·0368	5·76	< 0·00001

Table IV
Forward-difference coded regression table for four levels of heavies.

[11] This article focuses on rhyme structure, putting aside the question of whether onsets also contribute to weight. The issue of onset weight is addressed by Ryan (2011: 151ff).

[12] I benefited from the contr.sdif method in the MASS package (Ripley 2011) for R. In making predictions from a forward-difference coded table, one must sum not only the general intercept and the relevant coefficient, but also the coefficients of all preceding levels (see Ryan 2011: 24 for equations).

Finally, let us consider one additional level, namely VCC. Numerically, VCC patterns as intermediate between VV and VVC in biceps-skewness, but it is significantly different from neither, as Table V reveals.[13]

rhyme	comparandum	coefficient	standard error	z-value	p-value
intercept	i.e. V[obs]	−3·3572	1·4520	−2·31	= 0·021
V[son]	*vs.* V[obs]	0·2654	0·0342	7·77	< 0·00001
VV	*vs.* V[son]	0·2166	0·0261	8·30	< 0·00001
VCC	*vs.* VV	0·0054	0·1009	0·05	= 0·958
VVC	*vs.* VCC	0·2076	0·1054	1·97	= 0·049

Table V
Adding VCC to the model.

VCC is also not significantly different from V[sonorant] ($p = 0·02$; cf. note 13), but is significantly different from V[obstruent] ($p < 0·0001$).[14] (A non-significant effect is not positive evidence that the poets failed to distinguish the weights of two types; it merely indicates that the present corpus and methodology provide no evidence that they did.) The place of VCC in the hierarchy can be depicted in two dimensions using a Hasse diagram, as in (3), in which the implicit *x*-axis is biceps-skewness or weight. Solid lines indicate significant contrasts (in this case all $p < 0·0001$), broken lines near-significant contrasts, as annotated. Contrasts are transitive (e.g. V[son] < VVC is entailed).

(3) *Hasse diagram for five rhyme types*
In conclusion, the claim of West and others that the hexameter poets prefer to place heavier heavies in the biceps than in the longum is

---

[13] Although p is less than 0·05 for VCC < VVC, meeting the usual α criterion for significance, it is standard to use a more stringent criterion when multiple factors are tested as a suite. With the conservative Bonferroni correction (Abdi 2007), for instance, the criterion for significance is $0·05/4 = 0·0125$ in this case. Another point of conservatism is that all p-values reported in regression tables in this article are two-tailed, though one could perhaps make the case that one-tailed values are sufficient here.

[14] These p-values are not explicit in Table V, but can be determined either by coding the factors so that V[obstruent] and VCC are adjacent or by comparing their cumulative coefficients and standard errors.

corroborated here with an extensive parsed corpus and mixed effects modelling that factors out interference from word context and distribution. The poets are shown to be sensitive to a scale of weight within the heavies, as inferred from the relative skews of different rhyme types between longa and bicipitia. This scale aligns with the scale inferred from the cross-linguistic typologies of stress and other weight-sensitive phenomena (Gordon 2002, 2006). Moreover, it aligns with the weight scales established for the other metrical traditions examined in this article.

2 The Finnish Kalevala metre

2.1 Metrical and corpus preliminaries

The Kalevala is a Finnish epic poem based on Karelian folk songs compiled and edited in the nineteenth century by Elias Lönnrot (Lönnrot 1849). The metre is trochaic tetrameter, such that each line instantiates the abstract template in (4), which alternates between strong and weak positions. The final position, while in principle weak, can be regarded as anceps (unregulated), as it is in most quantitative metres (cf. §1.1).

(4) *Kalevala trochaic tetrameter template*

1		2		3		4	
s	w	s	w	s	w	s	w

A general rule for mapping syllable weight to metrical positions is given by Kiparsky (1968: 138) as: 'stressed syllables must be long on the downbeat and short on the upbeat' (for further analysis of the Kalevala metre, see Sadeniemi 1951, Kiparsky 1968 and Leino 1986, 1994). By stressed syllables, Kiparsky means primary stressed syllables, which are always word-initial in Finnish.[15] Downbeats are strong; upbeats weak. Orthographic words comprising only one mora are treated as stressless clitics here. Short (i.e. light) syllables end in short vowels (C_0V); all other syllables are long (i.e. heavy). Complex onsets are absent from Kalevala Finnish; thus, V(C)V is parsed V.(C)V, VCCV as VC.CV, and so forth. My parser does not resyllabify across words (see Ryan 2011: 71 for justification). (5) contains three sample scansions, with stressed syllables and their positions boxed.

---

[15] Ryan (2011: 81) argues that unstressed syllables are also regulated (albeit more weakly), though the point is not critical here, since the present Finnish models are based solely on stressed syllables.
Figure 3
Distribution of exceptions to the Kalevala weight-mapping
rule across non-final positions of the line.

(5) *Scansion of three lines from the Kalevala*

  a. vaka vanha väinämöinen   40.221

  s   w   s   w   s   w   s   w

  va | ka | van | ha | væi | næ møi nen

  b. kalanluinen kanteloinen   40.224

  s   w   s   w   s   w   s   w

  ka | lan lui nen | kan | te loi nen

  c. ei ollut osoajata   40.228

  s   w   s   w   s w s w

  ei | ol | lut | o | so a ja ta

As Kiparsky (1968) observes, and as the examples in (5) reinforce, the mapping rule is not entirely strict, especially early in the line. It is enforced increasingly stringently towards the end of the line. Figure 3 gives the number of exceptions in each position (omitting the final position, which is anceps), taking only stressed syllables into account. As the accompanying plot illustrates, the decline in exceptions is almost one-to-one (i.e. slope ≈ -1) if one counts them on a logarithmic scale.

  My Kalevala corpus comprises 15,846 octosyllabic lines extracted from the text.[16] A theoretical issue bears on the construction of this corpus: Kiparsky (1968) maintains that the Kalevala is metrified according to derivationally intermediate rather than surface phonology. Specifically, he claims that five phonological rules are ordered after the metrically relevant level. I constructed the present corpus so that it is irrelevant for

[16] http://www.kaapeli.fi/maailma/kalevala (accessed June 2009).

the present purposes whether Kiparsky (1968, 1972) is correct in his theory of presurface metrification (cf. Devine & Stephens 1975, Manaster Ramer 1981, 1994; philological issues are also raised: cf. Lauerma 2001). I accomplished this by retaining only lines whose surface forms either match their alleged metrification forms or else depart from them only in irrelevant ways. First, two of the rules, contraction and apocope, affect syllable count, so by taking only surface octosyllables, there is no possibility that either of these rules applied. If they had, the surface form would have fewer than eight syllables. Two other rules, vowel and consonant gemination, are addressed by excluding all lines whose surface form contains a sequence that might have been an outcome of either rule. These exclusions reduce size of the corpus by 11 % (from 17,890 lines to the present 15,846). Finally, the diphthongisation is immaterial for the present purposes, because diphthongs and long vowels are collapsed in the following tests.

## 2.2 Metrical sensitivity to intra-heavy weight in Finnish

Examining the exceptions to the Kalevala mapping rule more closely, the poets' versification choices are evidently influenced by sensitivity to a scale of weight within the heavies (*contra* Kiparsky 1968, Hanson & Kiparsky 1996: 293, 308). In particular, the poets tend to prefer lighter heavies in weak positions rather than in strong ones, an asymmetry from which one can extract an intra-heavy hierarchy.

Let us begin with the rhymes VC and VV, as we did in §1.2 with Greek. Table VI gives the incidence of each (as well as V for comparison) in strong *vs.* weak positions. Counts are based on all stressed syllables from line-medial positions (excluding the two peripheries, which are largely unregulated). Although VC and VV are both found in strong positions over 90 % of the time, the strong:weak ratio for VV is over twice as great as that of VC ($p < 0.0001$). Put differently, despite VC and VV being comparably frequent in word-initial, stressed position (counts in Table VI), if the poet places a stressed heavy in a weak position, he or she is over twice as likely to choose a VC rhyme than a VV one (compared to the baseline ratio from strong positions).

	strong	weak	% strong	strong:weak ratio
V	270	9,388	2·8	0·03
VC	13,438	871	93·9	15·43
VV	10,935	307	97·3	35·62

Table VI
Overrepresentations of VC in weak positions.
Figure 4
Negative correlation of VC share with position strength. VC is
relatively overrepresented in weak positions, which favour lights.

At the same time, however, VC and VV are much closer to each other in
weight than either is to V. Weight is therefore being treated as an interval
scale (Stevens 1946): multiple levels are distinguished, but they are far
from evenly spaced. In this case, the gap between V and VC, straddling
the traditional heavy–light cut-off, dwarfs the gap between VC and VV,
though both gaps are highly significant.

Further support for the poets' treatment of VC heavies as lighter than
other heavies across the positions in the line is given by the fact that the
percentage of heavies that is VC in each position correlates negatively with
the strength of the poets' preference for heavies in that position. The solid
line in Fig. 4 represents the latter (i.e. the percentage of stressed syllables
in each position that are heavy), with peaks in odd (strong) positions. The
broken line represents the VC share (i.e. the percentage of stressed heavies
that are VC), which exhibits the converse pattern, i.e. peaks in even (weak)
positions. In short, the poets consistently prefer lighter (e.g. VC) heavies
in weak positions.

Table VII is a logistic regression table for Finnish rhyme skeletons,
including V (i.e. light), VC, VV, VCC and VVC.[17] The outcome is
placement in a strong (1) *vs.* weak (0) position. Data from line-peripheral
positions are once again excluded. As in §1.4, word context is included as a
random effect ($n = 55$) and factors are forward-difference coded, to be in-
terpreted in row-wise succession.

---

[17] VV subsumes long vowels and diphthongs. The Hasse diagram below remains un-
altered if VV is confined to long vowels, putting diphthongs aside. VC of course
subsumes V[obstruent] and V[sonorant], which, when tested separately, were not
significantly different from each other ($p = 0.66$).

rhyme	comparandum	coefficient	standard error	z-value	p-value
intercept	i.e. V	1·9580	0·5215	3·75	= 0·0002
VC	*vs.* V	6·6892	0·0864	77·42	< 0·00001
VV	*vs.* VC	0·8702	0·0762	11·42	< 0·00001
VCC	*vs.* VV	0·1869	0·3235	0·58	= 0·57
VVC	*vs.* VCC	0·6493	0·3332	1·95	= 0·05

Table VII
Logistic model for skeletal structure in Finnish.

If one puts aside VCC, the hierarchy is V < VC < VV < VVC (for every link p < 0·0001).[18] VCC, for its part, is significantly different from VC (p < 0·0001) but not from VV (p = 0·57) or VVC (p = 0·05; cf. note 13). Note that VCC is relatively rare, comprising 1·7 % of heavies. (6) summarises these results as a Hasse diagram.

(6) *Hasse diagram for Finnish rhyme skeletons*
In conclusion, as with Homeric Greek, the Kalevala poets are evidently sensitive to a scale of weight. In terms of the skeletal structure of the rhyme, V < VC < VV < VVC and VC < VCC (all p < 0·0001) in both languages.

3 Old Norse *dróttkvætt* metre

Old Norse poetry (ca. 700–1300 CE) comprises two genres, Eddic and skaldic. I focus on the latter here, particularly the Old Icelandic *dróttkvætt*, the most widely attested skaldic metre. Modal line length is six syllables, though lines can be longer, due to the option of filling certain positions with two syllables. Every line ends with a heavy stressed syllable followed by an unstressed syllable. Because stress is almost uniformly word-initial (unstressed prefixes being relatively marginal; Russom 1998: 13ff), it follows that the line typically ends with a disyllabic, heavy-initial content word.

---

[18] As Ryan (2011: 76) demonstrates, the same hierarchy is derived independently from prose comparison (see note 8).

The metrical description of the preceding four positions is more vexed. Perhaps the simplest proposal is that of Craigie (1900: 381), who proposes two metrical templates for the *dróttkvætt*, SWSWSW (i.e. trochaic trimeter) and SSWWSW (adding an inversion, though see Getty 1998 for arguments that inversion does not necessarily implicate multiple templates). To this scheme, Árnason (1991: 124ff, 1998: 102) adds a third template, WSSWSW. A more elaborate and also more widely employed description ('still the model most commonly referred to by philologists'; Árnason 1998: 101) is Sievers' (1893) five-type taxonomy for Germanic verse; cf. Kuhn (1983) and Gade (1995) for revisions in this tradition. For the sake of illustration, I employ Árnason's (1991) system, as exemplified in (7). In this scheme, a strong position can only be filled by a stressed, heavy syllable, whereas weak positions are not as strictly regulated.

(7) *Scansion of three lines from the* dróttkvætt

    a. gróðr sá fylkir fáði
          s   w   s   w   s   w
        ˈgroːðr ˈsaː ˈfyl kir ˈfaː ði

    b. ungr stillir sá milli
          s   s   w w s   w
        ˈungr ˈstil lir ˈsaː ˈmil li

    c. svartskyggð bitu seggi
          s   s   w w s   w
        ˈsvart skyggð ˈbi tu ˈseg gi

Because syllabification is a vexed issue in Norse metrics, I consider two very distinct approaches, not with a view to arguing for one or the other, nor to suggest that the correct algorithm is necessarily either, but merely to show that even with two opposing extremes (and, by hypothesis, any more nuanced intermediate position), the same general trend in gradient weight is observed. At one extreme, onset maximisation (OM; as in (7)) prioritises building onsets that are as complex as the phonotactics permits, e.g. [hun.drað] (cf. Árnason 1991: 123 for a qualified version of this approach). At the other extreme, coda maximisation (CM) groups all consonants with the preceding vowel, if any, e.g. [hundr.að] (Hoffory 1889: 91, Beckman 1899: 68, Pipping 1903: 1, 1937, Kuhn 1983: 53, Gade 1995: 30).[19] Note the asymmetry between these approaches: while OM is reined in by phonotactics ([hun.drað], not *[hu.ndrað]), CM (in the tradition cited) is not.[20] The criterion for light *vs.* heavy depends on the algorithm. Under OM, the rhyme V alone is light. Under CM, V, VC and VV are light.

---

[19] In an independent vein of research, Steriade supports the same algorithm, terming the spans 'intervals' rather than 'syllables' (Steriade 2008, 2009b).

[20] As in Finnish, the parser here does not resyllabify across words (Gade 1995: 31), though this issue also deserves more scrutiny in Old Norse.

A corpus of 11,832 six-syllable *dróttkvætt* lines was obtained from the University of Sydney Skaldic Project.[21] Though the *dróttkvætt* is not confined to six syllables, retaining only six-syllable lines facilitates metrical parsing. Under Árnason's scheme, position 5 is always strong and positions 4 and 6 are always weak.[22] Additionally, position 3 is weak if and only if positions 1 and 2 are both strong (filled by stressed heavies). Because positions 1 and 2 are more variable (being SS, SW or WS), I put them aside here. Each syllable from the final four positions is coded for the skeletal structure of its rhyme (e.g. VC), its position type (1 for strong, 0 for weak) and its word context (as in §1.3). A logistic model then predicts metrical placement from rhyme type, factoring out word context as a random effect, as before.

Table VIII is the resulting regression table, at this point considering only stressed, word-initial syllables, as in Finnish (§2), and assuming OM. As always, the table is forward-difference coded, such that a positive coefficient indicates that the given rhyme type exhibits greater bias towards strong positions than the comparandum type. The hierarchy is thus V < VC < VV < VVC < VCC < VVCC (for every link p ≤ 0·0001).

| rhyme	comparandum	coefficient	standard error	z-value	p-value
intercept	i.e. V	−0·7075	0·7082	−1·00	= 0·32
VC	*vs.* V	0·3951	0·0561	7·04	< 0·00001
VV	*vs.* VC	0·2098	0·0482	4·35	= 0·00001
VVC	*vs.* VV	0·2800	0·0734	3·81	= 0·0001
VCC	*vs.* VVC	0·4788	0·0752	6·36	< 0·00001
VVCC	*vs.* VVC	0·4397	0·0902	4·87	< 0·00001

Table VIII
Logistic model for Old Norse stressed syllable placement.

The same basic hierarchy is observed (every link p < 0·0001) if CM is instead employed: VC < VCC < VVC < VVCC < VCCC < VVCCC (for every link p < 0·0001). An additional consonant is now appended to each rhyme to better align the OM and CM scales. For example, the initial rhyme of [rifu] is V under OM but VC under CM.[23] Figure 5 compares the two hierarchies graphically. To facilitate comparison, the intercepts are normalised to zero. To visualise the global trend, the forward-difference-coded coefficients are presented cumulatively (i.e. as sums of

---

[21] http://skaldic.arts.usyd.edu.au (accessed August 2010).

[22] It is not a consensus that the fourth position is always weak; see Árnason (1991: 139, 2009: 48) for discussion of the issues.

[23] This is not to imply that there is a biunique mapping between OM and CM rhymes, in which case they would be notational variants. Recall [hundrað], in which the initial rhyme is VC under OM and VCCC (not VCC) under CM. It merely reflects that V under OM is most frequently VC under CM, and so forth.
Figure 5
Weight coefficients under two syllabification algorithms.
Larger coefficients indicate a greater skew of stressed syllables
containing the given rhyme towards metrically strong positions.

coefficients up to and including the given rhyme). Rhymes on the *x*-axis are labelled according to both schemes, with OM on top. While it is not surprising that these scales are well correlated, this comparison demonstrates that the choice of syllabification algorithm does not qualitatively alter the conclusion concerning weight.

I now turn to unstressed (non-word-initial) syllables. Because they cannot occupy strong positions, strong/weak asymmetries cannot be used as a diagnostic, as they were above for stressed syllables. Instead, I capitalise on the increasing rigidity of the metre towards the end of the line. In particular, I compare unstressed syllables in positions 4 and 6, which are the final two weak positions and also the only two positions that are uniformly weak, to those in all other positions. The former are coded 0 and the latter 1, reflecting the hypothesis that unstressed syllables in uniformly weak cadential positions will tend to be the aggregately lighter set. The logistic model is otherwise set up as above.

Under OM, the following hierarchy emerges: V < VC < VV < VCC < VVC < VVCC (for every link p < 0·0002). Under CM, the same hierarchy emerges (for every link p < 0·0001, except VCC < VVC, which is p = 0·003). The coefficients under both schemes are plotted in Fig. 6, as they were in Fig. 5.

In conclusion, two tests reveal sensitivity to a scale of weight in *dróttkvætt* composition. First, the heavier a stressed syllable is, the more likely it is to be placed in a strong position, giving the scale V < VC < VV < VVC < VCC < VVCC. Second, the heavier an unstressed syllable is, the less likely it is to be placed in a cadential weak position, revealing the scale V < VC < VV < VCC < VVC < VVCC. These tests are
Figure 6
Weight coefficients under two syllabification algorithms.
Larger coefficients indicate a greater avoidance of unstressed syllables
containing the given rhyme in cadential weak positions.

independent of each other, relying on completely disjoint sets of data, yet reveal tightly correlated hierarchies. The one exception concerns the rhymes VCC and VVC, which are adjacent under both tests, but in opposite orders. The composite hierarchy is therefore V < VC < VV < {VCC, VVC} < VVCC (where the status of the braced pair is unclear), as in (8), consistent with the V < VC < VV < VVC scales in Ancient Greek and Finnish. Moreover, the present tests cast doubt on whether the *dróttkvætt* privileges any single binary criterion over the various other weight distinctions in the way that Ancient Greek and Finnish appear to.

(8) *Hasse diagram for Old Norse rhyme skeletons*
4 Tamil: Kamban̲'s epic metre

4.1 Metrical and corpus preliminaries

The fourth and final language examined in this article is Middle Tamil, specifically Kamban̲'s ca. 1200 CE epic poem, the *Irāmāyaṇam* (critical edition 1956), a Tamil telling of the South Asian Rāmāyaṇa epic (Hart &

Heifetz 1988).[24] A Unicode Tamil-script version of the poem was processed from the Tamil Electronic Library,[25] losslessly Romanised, and obtained (in part by applying sandhi rules, cf. Rajam 1992, Lehmann 1994) to be more phonetically transparent. The resulting text comprises 42,128 lines in 10,532 rhyming quatrains.

According to traditional accounts of Tamil prosody (e.g. Niklas 1988, Zvelebil 1989, Rajam 1992, Murugan 2000), syllable weight is binary, with C_0V being light. Complex onsets are forbidden, giving, for instance, V.V, V.CV, VC.CV, VCC.CV. A word-final consonant is resyllabified with a following vowel-initial word (in some editions, this is made explicit orthographically; Ryan, forthcoming). Diphthongs are treated here as V(ː)C sequences, where C is a glide [j] or [ʋ]. As such, they always scan as heavy, with two conditional exceptions: [aj] and (rare) [aʋ] are claimed to scan as heavy word-initially but light elsewhere (for similar situations in other languages see Miyashita 2002, Kiparsky 2003). These diphthongs, when light, are notated [ăj] and [ăʋ] here.

Kamban's epic comprises an indefinite variety of metres. To begin with two examples, the first and last couplets of the text are given in (9), in IPA transcription and in terms of syllable weight (H = heavy, L = light). Weight templates are spaced at word boundaries, with bullets indicating cæsuras. In these examples, syllable count per line matches within the two couplets but not between them. Furthermore, syllables tend to correspond in weight between lines of the same verse, as indicated by underlining, but across verses, the sequences have little in common.

(9) *Scansion of the first and last couplets of Kamban's epic*

     LHLL HL HL • HLH LLLHH
     LHLL HL HL • LLLH HLHH

Even for a given syllable count, templates vary widely across verses. Modal line length is 16 syllables (though only 15 % of lines are of modal length, underscoring the diversity of the corpus). Two 16-syllable verses are exemplified in (10). Position 4, for instance, is consistently heavy in the first, but light in the second. Indeed, the first verse might be characterised as 16 periods (four per line) of LLLH, the second, perhaps, as eight periods of LLLLLLHX. In short, even considering only lines of a certain

---

[24] The names of this work and poet can be found cited as several variants, including *Irāmāyaṇam* (with or without the initial *i* and final *m*), *Irāmāvatāram* (same caveat), Kambar, Kampar and Kampan.

[25] http://tamillibrary.org (accessed June 2009).

syllable count, one is hard pressed to define globally applicable strong and
weak positions.

4.2 Scalar weight in Tamil metrics

For the present purposes, it is unnecessary to provide a complete model of
the metrics in order to gain insight on the treatment of syllable weight.
One can capitalise on the templatic parallelism between lines within verses
to observe how syllables pattern with respect to each other in terms of
weight. As a preliminary illustration, Fig. 7 depicts the estimated weights
of syllable types as inferred from their rates of correspondence with heav-
ies in parallel positions of matched-length couplets. For example, in the
two verses in (10), the syllable [ka] is found (after resyllabification) four
times, couplet-corresponding to [ja], [ji], [ɻe] and [n̠i] respectively, a
heavy response rate of 0 %. In Fig. 7, the *x*-axis is the percentage of the
time that each syllable type corresponds to heavies across the whole cor-
pus. Only the 115 most frequent types are shown, corresponding to a
frequency cut-off of 500.

    Though one might get an initial impression of light (left) and heavy
(right) clouds from Fig. 7, additional stratification is readily observed.
Traversing the plot from left to right, syllables can be divided into at least
the following relatively coherent (if overlapping) groups: C_0V (true
lights), C_0ăj (light diphthong), C_0VR (R = rhotic, i.e. [ɾ] and [ɻ] in this
dialect), C_0VN (N = nasal) and $C_0V{:}C_0$ (syllables with long vowels).[26]

---

[26] Only two obstruent-final syllables, [kaṯ] and [ɾak], appear in the plot. Both are on
the lighter side of the heavies, but I set them aside for the moment, given the small
sample size.

Figure 7

Correspondence-estimated weights of 115 Tamil syllables. The *x*-axis
is the percentage of the time that each syllable type is paired with a heavy
syllable in the corresponding position of a matched-length couplet.

Figure 8 makes this clustering explicit by sorting Fig. 7 into five layers,
one for each category, as labelled on the left. The *x*-axis, which is constant
through the subplots, is the same as in Fig. 7. The *y*-axes of subplots are
rescaled to fit their data. For all the corpus data (and not just the smaller
set of frequent syllables shown in the figures), the four pairwise compar-
isons between groups are all significant at (Fisher's) p < 0·00001.

   Linear regression provides a more controlled means of estimating the
effective weights of syllable types from their corpus distributions, corro-
borating the results above. Most of the model is set up as in previous
sections, with rhyme shapes as factors and word contexts as random ef-
fects (§1.3). The outcome in this case is a continuous, real-valued variable,
reflecting an estimate of the strength of the position in which each syllable
token is placed. The general idea is that if one wishes to determine whe-
ther a given position in a given line is strong or weak, one can observe to
what extent the same context in similar lines is filled by a heavy as opposed
to a light syllable.

   Given this approach, one must define a metric or criterion for similarity.
One simple criterion is templatic identity. For example, the strength of the
third (gapped) position of the line LL __ HLHLLLH can be estimated

Figure 8

Figure 7 filtered into five phonological classes.

from the incidence of heavies in the same position across lines with the same template. Nevertheless, with such a stringent criterion for similarity, the mean for comparanda per datum is only 2·9 lines; the corpus exhibits 14,503 different templates (ignoring boundaries). To increase the number of comparanda per datum, one can restrict one's attention to a more local part of the line, such as, say, a five-syllable window centred on the position of interest. (11) exemplifies two 16-syllable lines with the frame LL __ HL at position 7.[27] Only lines with identical lengths are compared, so that the

[27] As the figure suggests, frames ignore word boundaries, but it should be borne in mind that word context is still employed by the model as a random effect. For

alignment of windows is commensurate. With five-syllable windows, mean comparanda per datum is 148.

(11) *Five-syllable window for line comparison*
   a. original line   ilăj kulaːv aji |li|naːn anikam eːɻ ena ʋulaːm
       spaced weight template LL LH LL __ H LLL H LL LH
       comparandum filter   XXXXLL __ HLXXXXXXX
   b. original line   aruɳṭaṭi janăj |jaː| ɭeː jamuṭinum inijaːɭeː
       spaced weight template LHLL LL __ H LLLL LLHH
       comparandum filter   XXXXLL __ HLXXXXXXX

For the present linear model, then, the outcome is the log ratio heavy/light among the set of eligible comparanda, where eligibility is determined by a five-syllable window.[28] The higher the log ratio, the more often Kamban places a heavy in the given context. Ten rhymal categories are considered in Table IX, forward-difference coded, as before (§1.4).

rhyme	comparandum	coefficient	standard error	t-value	p-value
intercept	i.e. V	0·1411	0·0288	4·90	< 0·00001
ăj	*vs.* V	0·2896	0·0074	39·26	< 0·00001
VR	*vs.* ăj	0·1038	0·0140	7·43	< 0·00001
VT	*vs.* VR	0·5414	0·0134	40·30	< 0·00001
VN	*vs.* VT	0·2381	0·0070	33·92	< 0·00001
VL	*vs.* VN	0·3290	0·0127	25·98	< 0·00001
VJ	*vs.* VL	0·1466	0·0200	7·37	< 0·00001
V:	*vs.* VJ	0·0128	0·0168	0·77	= 0·44
V:C	*vs.* V:	0·1130	0·0090	12·58	< 0·00001
V:CC	*vs.* V:C	0·2033	0·0240	8·47	< 0·00001

Table IX
A ten-level linear regression for Tamil weight.

positions close enough to the line periphery that the window would exceed the edge, boundary symbols are used in lieu of H or L.

[28] Given the flexibility of the metre and the number of comparanda, a zero numerator or denominator is rarely an issue in taking this log ratio. Nevertheless, tokens with no heavy or no light comparanda are excluded for this reason, reducing usable data by no more than 0·25 %. The log ratio rather than proportion is used, so that the distribution of outcomes is closer to normal and the model is more sensitive to differences at the extremes, counteracting ceiling/floor effects. This method assumes the traditional heavy/light criterion as a prior, both in estimating positional strengths and in coding for word context. As Ryan (2011: 32) demonstrates, this assumption is unnecessary; even with other priors (e.g. a cut-off between VC and VV instead of between V and VC), the end result is qualitatively almost identical.

Of these ten levels, nine reach significance: $V < \breve{a}j < VR < VT < VN < VL < \{VJ, V\!:\} < V\!:C < V\!:CC$ (all $p < 0\!\cdot\!00001$). The coefficients are plotted to scale in (12). This scale is consistent with those derived in the previous sections for Ancient Greek, Finnish and Old Norse, all of which exhibit $V < VC < VV < VVC$.
(12) *Estimated weights of the rhyme types in Table IX*
4.3 Motivating the Tamil scale

As discussed in §1.4 for Ancient Greek, two general principles of weight are that increasing complexity and increasing sonority are both associated with, if anything, greater weight. These principles jointly motivate most aspects of the Tamil hierarchy in (12). First, in terms of timing slots, the scale reduces to monotonic $X < XX < XXX < XXXX$ (cf. Hayes 1979: 196 on an $X < XX < XXX$ hierarchy in Persian metre).[29] Second, within XX rhymes, the scale is largely explicable in terms of sonority. (13) uses association lines to show the alignment between a cross-linguistically typical sonority scale (Hogg & McCully 1987: 33, Parker 2002) and the scale inferred from Tamil metrics. With the exception of the rhotics, the two scales align.

(13) *Typical sonority scale* (a) vs. *Tamil metrics* (b)

    a. $\emptyset$ < obstruent < nasal < lateral < rhotic < glide < vowel

    b. light < rhotic < obstruent < nasal < lateral < glide, vowel

    Two details of the Tamil hierarchy remain to be explained. First, the light diphthong [ăj], if segmentally complex, would be expected to be near VJ, not V. Second, and more intriguingly, rhotic codas pattern as unexpectedly light, given their high sonority. I first show that an independent phonological system, prosodic minimality, also treats VR rhymes as light, in opposition to $VC_{\neq R}$ and V:. I then propose that the relatively light weights of VJ and VR are grounded by their short durations.

    Like Latin (Mester 1994), Tamil exhibits a bimoraic minimum for all word types, as supported by the systematic absence of light words (cf. Ketner 2006), by certain length alternations (e.g. [ʋa-ɾa] 'come-INF' *vs.* [ʋaː] 'come (IMP)'; cf. Prince & Smolensky 1993, Blumenfeld 2010), and by loanword adaptation. As Ryan (2011: 107) argues, C_0VR (where

---

[29] This remains true regardless of whether the diphthong [ăj] is treated as one or two segments.
Figure 9
Metrical weight (*y*-axis) as a function of rhyme duration (*x*-axis).

$R \in \{\mathfrak{r}, \underline{\mathfrak{t}}\}$, as above) is subminimal, while C_0VC with any other coda is not. In a C_0VR monosyllable, V must be long. This restriction is evidently prosodic, given that vowel length is otherwise contrastive in C_0VR syllables in all positions of polysyllabic words. At the same time, several phonetic and phonological criteria converge on the rhotics being highly sonorous, and, as typologically expected, intermediate between the laterals and glides; they are also argued to be coda consonants, as opposed to part of the nucleus (2011: 107).[30]

As a preliminary assessment of the correlation between phonetic properties and metrical weight, Ryan (2011: 119) collected phonetic data on 351 consecutive syllables in a recording of high-register Tamil (the standard acrolect *cen-tamiḻ*; Tamil is diglossic), specifically, Kausalya Hart reading passages in the audio supplements to her Tamil textbook (Hart 1999). Though several centuries separate this recording from Kamban, pronunciation of the acrolect has evidently changed relatively little, as evidenced in part by its faithfulness to the orthography, which was largely settled by Kamban's time (Ryan 2011: 119). To the extent that pronunciation has changed, this comparison is over-conservative: one would expect the correlations reported below to be (if anything) stronger if the phonetic and poetic corpora were more closely aligned.

---

[30] Minimality is mute on the weight of [ăj], as it is found as such only non-word-initially (see §4.1).
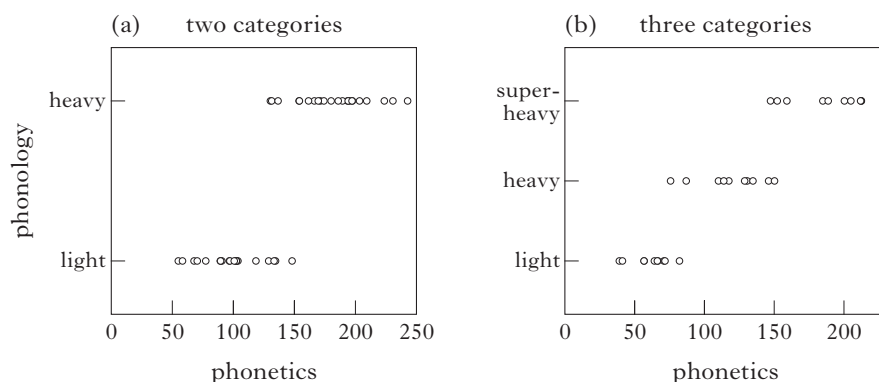

Figure 10
Figure 9 in terms of category means.

Figure 9 plots the durations of rhyme tokens on the *x*-axis against their inferred metrical weights on the *y*-axis (on the connection between duration and syllable weight, see Maddieson 1993, Hubbard 1994, Broselow *et al*. 1997, Gordon 2006). Duration was measured following Gordon (2002), using discontinuities in the spectrogram and waveform. For syllables closed by a geminate, the midpoint of the geminate was taken to be the endpoint of the rhyme. The weight of each rhyme type was estimated from the metrical corpus using the linear regression model in §4.2, except with individual rhyme types assessed as factors. The range on this axis is close to (0, 1), because the model's log odds estimates are translated into probabilities. The plot contains 351 points, one for each phonetic token. Some horizontal stratification is visible when several phonetic tokens instantiate the same rhyme. Three regression lines are shown. The longest is the overall correlation for all points (Pearson's correlation $r = 0.840$, Spearman's rank correlation $\rho = 0.847$; both $p < 0.0001$). The two shorter regression lines are based on the heavy and light points taken separately, revealing significant correlations even within each of the binary subsets ($r, \rho > 0.45$ for both; all $p < 0.0001$).

This plot reveals that metrical weight is largely ($r = 0.84$) predictable from rhymal duration.[31] Moreover, the treatment of [ăj] and VR rhymes as relatively light finds a phonetic motivation. Figure 10 is based on the same data as Fig. 9, but shows category means for the categories from §4.2 for which $n > 10$ in the phonetic data ($r = 0.929$, $\rho = 0.976$; both $p < 0.001$). Crucially, 'diphthong' (i.e. [ăj]) and 'rhotic' (i.e. VR) are the two categories nearest to V, on both the metrical and phonetic dimensions. Thus, the subhierarchy V < ăj < VR < VT is significant not only in the

---

[31] As Ryan (2011: 124) discusses, an even closer fit (including a correction of the mismatch between nasals and laterals in Fig. 10) is achieved if one integrates duration and perceptual energy (as advocated by Gordon 2002, 2006, Gordon *et al*. 2008), rather than relying on duration alone.

Figure 11
Phonetics–phonology interface under total categorisation.
(a) two weight categories (light and heavy);
(b) three weight categories (light, heavy and superheavy).

metrics (§4.2), but also in the phonetics (respective sample sizes of the four categories: 171, 28, 19, 63; respective *t*-test one-tailed *p*-values for the three contrasts: $p < 0.001$, $p = 0.020$, $p = 0.018$).

In conclusion, Kamban's metrical behaviour suggests sensitivity to a gradient continuum of weight, such that (at least) $V < \breve{a}j < VR < VT < VN < VL < \{VJ, V{:}\} < V{:}C < V{:}CC$ (for every contrast $p < 0.00001$). In terms of skeletal structure, this is the same scale established for Ancient Greek, Finnish and Old Norse: $V < VC < VV < VVC$. The subhierarchy within VC in Tamil ($R < T < N < L < J$) is explicable in terms of sonority, with the exception of the rhotics, which, despite being sonorants, pattern as the lightest codas. Minimality also treats VR as lighter than $VC_{\neq R}$. I propose that the light weights of VR and [ăj] are motivated by their short durations (or energies integrated over duration; note 31).

5 Weight mapping in metre

5.1 Varying categoricity in the treatment of weight

I now turn to the treatment of gradient weight in a generative model of weight mapping. Following work in generative metrics (e.g. Halle 1970, Halle & Keyser 1971, Kiparsky 1977, Hayes 1988, Hanson & Kiparsky 1996), I assume that metres comprise abstract templates of strong and weak positions (§2.1), among other structure. Constraints indexed to these positions define the sets of syllables permitted in them (e.g. *HEAVY/W: 'penalise a heavy syllable in a weak position'). By WEIGHT MAPPING, I refer to this correspondence relation between metrical positions and syllabic weight.

I begin by schematising a space of logical possibilities. At one extreme, weight mapping might be fully categorical. Figure 11 illustrates
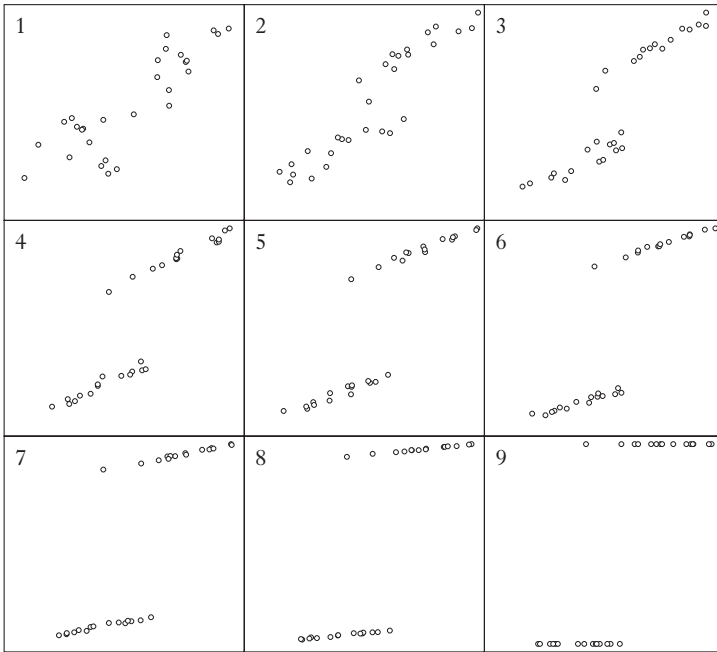

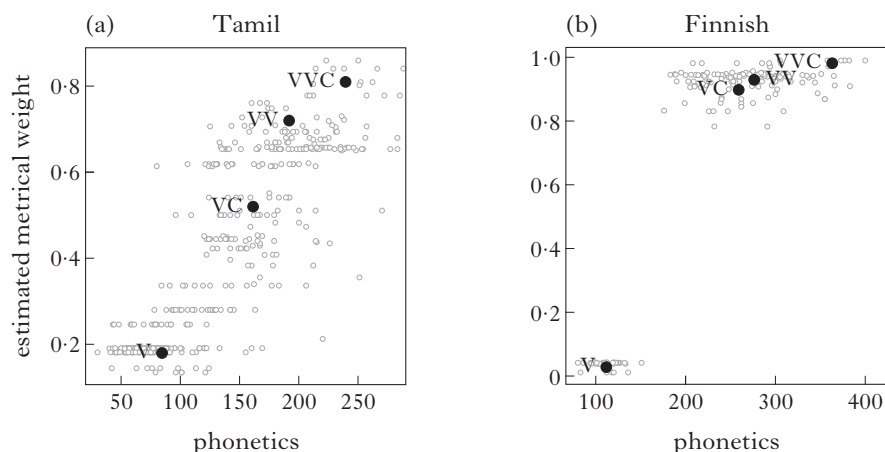

Figure 12
A continuum from no (plot 1) to total (plot 9) categorisation.
As categoricity increases, the correlation weakens between the
phonetic (*x*-axes) and phonological (*y*-axes) distributions.

hypothetical binary (a) and ternary (b) categorisations of dummy data
(sampled from normal distributions) on an arbitrary perceptual-phonetic
scale (*x*-axis).[32] These plots are organised like Fig. 9 above, in which
the *y*-axis is weight (a phonological variable) and the *x*-axis duration
(a phonetic variable). The categories in Fig. 11 overlap somewhat on the
phonetic dimension, representing, let us say, a bias for phonological sim-
plicity in categorisation at the expense of fidelity to the phonetic scale
(Hayes 1999, Gordon 2002).

At the other extreme, one can imagine that the phonology (*y*-axis) might
directly reflect the relevant perceptual-phonetic scale without any inter-
ference from categorisation (cf. Steriade 2000, 2001, Flemming 2001,
2003, 2004), as illustrated by plot 1 of Fig. 12. In this plot, the correlation
between phonetics (*x*-axis) and phonology (*y*-axis) approximates the
diagonal (adding noise for realism). As the other plots in Fig. 12 suggest,
one can also imagine situations intermediate between these two extremes,
in which the phonology is polarised towards categories, but continues to

[32] Yana stress (stress the leftmost heavy, if any, otherwise initial; Sapir & Swadesh
1960) exemplifies a fully categorical binary system. Kashmiri stress (Morén 2000) is
ostensibly a ternary case.

Figure 13
Differing categoricity in Tamil (Kamba̠n) *vs.* Finnish (Kalevala) metres.
Plots arranged as in Fig. 9.

reflect gradient sensitivity to a phonetic scale within categories. I term this intermediate situation INCOMPLETE CATEGORISATION (not to be confused with overlapping but complete categorisation, as in Fig. 11). The plots in Fig. 12 are arranged from the least categorical (plot 1) to the most (plot 9); cf. Fig. 11.[33]

Metres evidently vary in the extent to which they treat weight as binary-categorical as opposed to gradient, instantiating different points along the continuum of categoricity sketched in Fig. 12. Impressionistically, weight appears to be highly (though not exclusively) categorical in Homer's epics (§1) and the Kalevala (§2), but less so in Kamba̠n's epic (§4), in which it is not obvious that categorisation plays any role. More concretely, compare the Tamil (a) and Finnish (b) distributions in Fig. 13. In both plots, the means for V, VC, VV and VVC are superimposed on grey circles representing rhyme tokens. The Tamil data are repeated from Figs 9 and 10, with the same organisation. The Finnish rhyme weights (*y*-axis) are estimated from the logistic model in §2.2 (see also Table VI), while their durations (*x*-axis) are based on a small auditory corpus.[34] In both plots, the data are relatively continuous on the phonetic dimension (as also seen in Gordon's 2006 Finnish data). They differ mainly on the metrical dimension. The Tamil data are continuous, with VC (whether including or excluding VR; §4.3) being approximately halfway between V and VVC. The Finnish data, by contrast, are widely separated, with VC being over

---

[33] Similar distributions are analysed in connection to experiments on categorical perception (e.g. DiCanio, forthcoming and references therein).

[34] Specifically, 162 stressed syllables were measured from WAV files of a native speaker (Kai Nikulainen) pronouncing Finnish words in isolation for pedagogical purposes (www.sci.fi/~kajun/finns/Samples; accessed May 2011). The speech rate is generally slower than in the Tamil data.

ten times as close to VVC as it is to V.[35] At the same time, weight is not exclusively binary in Finnish, as the contrasts in $VC < VV < VVC$ are significant (§2).

As a constraint framework capable of handling gradient variation, I employ maximum entropy (maxent) grammar (Johnson 2002, Goldwater & Johnson 2003, Wilson 2006, Jäger 2007, Hayes & Wilson 2008, Ryan 2010, Hayes & Moore-Cantwell 2011; cf. Boersma & Pater 2008), a type of Harmonic Grammar (Smolensky & Legendre 2006, Pater 2009, Potts *et al.* 2010), but with probabilistic interpretation of candidate harmonies and often a Bayesian approach to constraint weighting. As in all varieties of Harmonic Grammar, the score of each candidate is the sum of its weighted violations. In maxent grammar, rather than treating the candidate with the greatest score as the categorical winner, all scores are transformed into probabilities (though often ones so close to zero or one that the output is effectively categorical). Specifically, if s_i is a candidate's non-negative penalty score, $p(\text{candidate}) = e^{-s_i}/\sum_j e^{-s_j}$, where j ranges over all candidates. Constraints are weighted so as to maximise the likelihood of the observed distribution of outputs, possibly with smoothing. See the references above for a more detailed overview.

Incomplete categorisation can be modelled in such a framework by the interaction of categorical and scalar constraints. A fully categorical distribution (as in plot 9 in Fig. 12) is modelled by giving the relevant categorical constraints positive weights and scalar constraints zero weights. A direct interface distribution (as in plot 1) can be achieved by giving scalar constraints positive weights and categorical constraints zero weights. Incomplete categorisation emerges if both categorical and scalar constraints are given positive weights (e.g. plots 2 through 8, according to their relative weights).

A categorical constraint (e.g. *Heavy/w) is either violated or not for each locus of violation; it cannot be violated multiple times (or to some other degree) by a single locus (McCarthy 2003). A scalar (also known as gradient) constraint, by contrast, is violable to a greater or lesser degree by a single locus (e.g. Flemming 2001, Pater, forthcoming). In the present case, scalar constraints are labelled with the comparative suffix (e.g. *Heavier/w) and violated to a real-valued degree supplied by the phonetics (as in Flemming 2001; cf. the more abstract integer scale for sonority implied by HNuc; Prince & Smolensky 1993, McCarthy 2003, Pater, forthcoming).[36] For the sake of illustration, the phonetic model here is based on the log mean duration of the rhyme, though a more accurate

---

[35] Categoricity is orthogonal to the range on the *y*-axis, which corresponds to the overall strictness of the metre. If the difference between strong and weak positions were attenuated, the points would approach a horizontal band. Thus, while strictness of the metre corresponds to the slope of the regression line in such a plot, categoricity concerns only the degree of polarisation on that continuum.

[36] While McCarthy (2003) argues for the exclusion of scalar (in the present sense) constraints from Optimality Theory, Pater (forthcoming) maintains that they are appropriate for (serial) Harmonic Grammar. Flemming (2001) is also couched in Harmonic Grammar, not Optimality Theory.

model would likely be perceptually grounded, integrating loudness, auditory recovery, and so forth (Gordon 2005, Crosswhite 2006, Gordon *et al.* 2008).

(14) is a maxent tableau illustrating four candidate lines for the Kalevala metre. Lines (a) and (b) are actually from the Kalevala, while (c) and (d) are octosyllabic snippets extracted from prose, included for comparison. Four mapping constraints are given in the top row, in decreasing order of weight. For the Kalevala metre, they evaluate only stressed (i.e. word-initial) syllables, excluding those in line-initial position (cf. Sadeniemi 1951, Kiparsky 1968; see §2.1). The first two constraints, *Heavy/w and *Light/s, are categorical (as above). The final two, *Heavier/w and *Lighter/s, are their scalar counterparts, whose violations are real numbers generated by a phonetic function representing the weight percept. For the present purposes, this function is based solely on the log mean durations of rhyme types, as estimated from the auditory corpus above (note 34). In particular, for each locus of violation, the scalar constraint is violated by the locus's distance from the unmarked end of the scale (cf. McCarthy's 2003: 82 paraphrase of HNuc). Here, the extrema are taken to be the minimum and maximum log mean durations ($\log(88 \text{ ms}) = 4\cdot48$ and $\log(408 \text{ ms}) = 6\cdot01$).[37] Consider, for example, the stressed rhyme *at* in candidate line (a). Because *at* occupies a weak position, it violates both *Heavy/w (by 1) and *Heavier/w (by $\log(264 \text{ ms}) - \log(88 \text{ ms}) = 1\cdot099$). Note that the violation is the same if seconds or some other unit is used instead of milliseconds: $\log(0\cdot264 \text{ sec}) - \log(0\cdot088 \text{ sec}) = 1\cdot099$. If a rhyme type is absent from the present data, the mean of its skeletal type is substituted.

(14) *Illustrative maxent tableau for the Kalevala metre*

	*Heavy/w 1·348	*Light/s 1·055	*Heavier/w 0·449	*Lighter/s 0·252	pen-alty	p
a. paksumpi pat-sasta portin	1	0	1·10	0·54	1·98	0·06
b. souti seppo ilmarinen	0	0	0·00	0·80	0·20	0·35
c. asti næmæt ovat hamin	0	3	0·00	3·93	4·16	0·00
d. olla minæ teːn hænelle	0	1	0·20	1·42	1·50	0·08

[37] Calibrating durations against the extrema has the potential virtue that the violation for a single locus is in practice bounded by the range $[0, c]$, where c is a smallish real, 1·53 here (though in principle, the maximum mean duration of a syllable type is unbounded). Other calibrations are conceivable. For example, one might use the grand mean instead of the extrema, subtracting or adding as necessary. On this approach, violations would drift into negative ('reward') territory for loci on the unmarked side of the mean.

Line (a) also contains one stressed syllable in a (non-initial) strong position, namely *pór*. Although this is a heavy syllable, satisfying *LIGHT/S, it still receives a small penalty from *LIGHTER/S for its distance from the heavy extremum $(\log(408 \text{ ms}) - \log(238 \text{ ms}) = 0 \cdot 539)$. Constraint weights (computed using the maxent grammar tool (Wilson & George 2008), with $\mu = 0$ and $\sigma^2 = 1000$) are given under their labels. To compute the penalty for line (a), its violation vector $<1, 0, 1 \cdot 1, 0 \cdot 54>$ is multiplied by the constraint weight vector $<1 \cdot 348, 1 \cdot 055, 0 \cdot 449, 0 \cdot 252>$, and the result $<1 \cdot 348, 0, 0 \cdot 49, 0 \cdot 14>$ is summed, giving $1 \cdot 98$. The given *p*-value represents in this case the proportion of lines in the corpus with penalties higher than the candidate's. Thus, p = 0 for line (c) (from prose) indicates that no line of the Kalevala has that high a penalty. Line (d), while also from prose, is as harmonic as almost 10% of Kalevala lines by this metric. This cline of harmony recalls the notions of complexity (Halle & Keyser 1971) and gradient metricality (Hayes 1989b, Youmans 1989). Finally, note that this grammar is not a complete model of Kalevala weight mapping. For one, it ignores the fact that violations become increasingly costly towards the end of the line (§2.1); it also sets aside the apparently weaker constraints on unstressed syllables (note 15).[38]

Though constraints such as categorical *HEAVY/W and scalar *HEAVIER/W partially overlap in their workloads, their coexistence generates a typology in which categoricity can vary across systems. An independent argument for the simultaneity of categorical and gradient weight concerns metres such as the Homeric hexameter. Recall from §1.1 that the metre contains two position types, the longum and the biceps, both of which, if filled by a single syllable, permit only a heavy.[39] In this respect, the metre is categorical in its treatment of lights and heavies, as could be modelled under the present theory by giving constraints such as *LIGHT/ BICEPS and *LIGHT/LONGUM sufficiently high weights.[40] At the same time, however, a clear weight gradient is observed within the heavies, such that the heavier the heavy, the more skewed it is towards the biceps, all else being equal (§1.4). To model this difference, the weight of *LIGHTER/ BICEPS can exceed that of *LIGHTER/LONGUM, such that lighter heavies incur greater penalties in bicipitia.

(15) is a maxent tableau for the hexameter. Since no phonetic corpus is available, for the sake of exposition, the Finnish data used above are also recruited here (as above, if a rhyme type is absent from the data, the

---

[38] Increasing stringency can be modelled either by cloning the relevant constraints for each position or by including position as a variable in the constraint's violation function (i.e. definition), such that violations in later positions are amplified. Likewise, for unstressed syllables, one could either add constraints indexed to them (or to all syllables), or else build stress level into the violation function.

[39] Exceptions can be found, especially in the first metron (note 4); elsewhere, they are rare. Exceptionality is generally trivial to model in maxent grammar, in which near-categorical constraints can be precisely weighted such that a suitably tiny proportion of the probability mass is allotted to such cases.

[40] To avoid confusion, I avoid labelling the hexameter position types strong and weak, though this is not to imply that they cannot be reformulated in such terms.

skeletal mean stands in). Even though the categorical constraints are rarely violated, they need not be given the highest weights, since they overlap ('gang up') with their scalar counterparts in eliminating lights. Note that the grammar as stated is incomplete; for instance, it ignores the possibility of filling a biceps with a pair of lights, focusing only on the treatment of syllable weight.

(15) *Illustrative maxent tableau for the Homeric hexameter*

	*Lighter /Biceps 4·071	*Light /Biceps 3·557	*Lighter /Longum 3·522	*Light /Longum 3·324	pen- alty	p
a. triplɛːj tetraplɛːj t' apotejsomen aj ke potʰi zdews	0·48	0	2·48	0	10·69	0·53
b. ej tar ʰo g' ewkʰɔːlɛːs epimempʰetaj ɛːd' ʰekatombɛːs	0·38	0	2·53	0	10·46	0·55

In sum, categorisation and a gradient phonetic interface are argued to interact in weight mapping. First, categorisation can be incomplete, in which case polarisation towards categories is evident, but not so absolute that the grammar is insensitive to the underlying phonetic scale within categories. Second, even if categorisation is complete, it can still be accompanied by intra-categorial gradience, as in the hexameter, which exhibits both a strict binary cut-off and sensitivity to a continuum of weight within the heavies.

5.2 On other possible approaches

As an alternative approach to gradient weight, consider first a theory under which weight is exclusively binary, but syllables are assigned to categories probabilistically, perhaps owing to variable mora projection (on non-variable mora-based weight, see Hyman 1985, Zec 1988, Hayes 1989a, Steriade 1991, Gordon 2002). For example, the coda of a VC rhyme might exhibit, say, a 90% chance of projecting a mora, while the second timing slot of VV might exhibit greater odds, such that the latter patterns as slightly heavier. More technically, the question is whether the grammar treats gradient weight as a continuous variable (as proposed in §5.1) or as a discrete (also known as Bernoulli) random variable.

The Greek hexameter furnishes an empirical argument against intra-heavy weight as variable binary weight. As discussed in §5.1, an intra-heavy scale is evident even among positions in which light syllables are categorically forbidden. In the fifth metron, for instance, the VC share of heavies is 69% higher in the longum than in the biceps, even though neither position can be filled by a light (West 1970). For an analysis in terms of variable binary weight, we can assume that progressively lighter heavies are progressively more likely to be categorised as light, while the

lighter status of the longum is motivated by its being more tolerant of lights than the biceps. From this analysis, it follows that lighter heavies (e.g. VT and VN) should be found more than occasionally in light positions in the fifth metron, as should true lights (rhyme V) in the fifth longum. Both predictions are incorrect.

Such an approach would likely also treat timing slots individually, which I term ATOMISATION, rather than considering properties of the whole rhyme as an unanalysed unit, as I did in §5.1. Even without reference to moras, one can imagine an atomised version of the approach in §5.1. In Tamil, for example, *GLIDE-CODA/W could outweigh *LATERAL-CODA/W, motivating the lighter treatment of VL *vis-à-vis* VJ. (For strong positions, in which VJ is the less marked, *LATERAL-CODA/S could outweigh *GLIDE-CODA/S.) The approach in §5.1 is simpler and more restrictive. First, under atomisation, cases like Tamil would require (at least) several constraints to replicate the work done by a single constraint in §5.1, though it is difficult to say precisely how many. Is there a different constraint for each coda consonant? If not, how are consonants grouped? These sorts of questions are moot in §5.1. Indeed, the distributions in §4.3 suggest that Tamil weight is continuous, rather than discretised into even several well-defined levels. One can always approximate a continuous distribution by superimposing increasingly fine-grained categories on it, though if the distribution reflects an intrinsically gradient variable, such an exercise is analytically extravagant.

Moreover, atomisation risks massive overgeneration. For instance, one could generate Tamil′, a language phonetically identical to Tamil, except in that its metrics treats VL as heavier than VJ, reversing the weights of the aforementioned constraints. To avoid this problem, one might (i) stipulate a fixed ordering of constraints, (ii) project constraint weights from a phonetic model or (iii) reformulate the constraints in terms of a stringency hierarchy. I address these three analytical tacks in turn.

First, fixing the ordering amounts to adding a set of stipulations that were unnecessary in §5.1. Furthermore, even with a fixed ordering, metres are generated in which position types exhibit unrelated patterns of conflation, e.g. one in which weight is strictly binary, but the cut-off falls between VL and VJ for weak positions and between VT and VN for strong positions. Such a metre is compatible with the hierarchy T < L < J, etc. In §5.1, by contrast, the binary criterion (if any) is constant (assuming that the shorthand predicates 'light' and 'heavy' are by definition complementary), and all scalar constraints access the same phonetic scale. (See also de Lacy 2004 *contra* fixed rankings.)

Second, one might project constraint weights from a phonetic model (cf. Steriade 2009a on projection in Optimality Theory), avoiding some of the aforementioned overgeneration problems (e.g. Tamil′), as well as the need for scalar constraints. However, the questions concerning the number and division of categories persist, as do the methodological concerns regarding the explosion of the constraint set in an attempt to simulate a continuous distribution (cf. Zhang 2007). Moreover, even insofar as this

approach approximates a notational variant of §5.1, it is more complex on multiple dimensions, in that it requires both many more constraints and an additional grammatical component to project their weights.

Finally, expressing constraints in terms of a universal stringency hierarchy avoids some overgeneration issues (e.g. Tamil′) and arguably possesses theoretical and empirical advantages over fixed rankings (Prince 1999, de Lacy 2002, 2004). Since heaviness is marked in weak positions, for instance, a stringent weak-indexed constraint would penalise not only a particular rhyme, but any and all heavier rhymes (e.g. *VL-OR-HEAVIER/W, *VN-OR-HEAVIER/W). Such constraints can be freely ranked, producing various patterns of conflation, but never markedness reversals (as with Tamil′). Several of the problems outlined above also apply to stringency. For one, stringency overgenerates discrepant patterns of conflation for strong *vs.* weak positions. Further, it requires many more constraints than §5.1, including at least 18 for Tamil (nine levels in §4.2 × two position types), though perhaps many more, considering that the hierarchy in principle subsumes any weight distinction significant in any language. The universal hierarchy is itself problematic. Consider, for instance, the fact that VR is lighter than VT in Kamban (§4), but heavier than it in Homer (§1). If this difference is phonetically grounded, the approach in §5.1 gets it for free. A stringency approach, by contrast, can accommodate such superficial reversals only by adding complexity to the universal hierarchy (e.g. distinguishing between shorter and longer rhotics), further recapitulating the phonetics. Finally, the theory in §5.1 predicts that weight should reflect the phonetics not only in terms of the rank order of rhyme types, but also in terms of the magnitudes of various contrasts (e.g. in (12), $VR < VT$ and $VT < VN$ are both significant, though the magnitude of former difference is over twice as great as that of the latter). Because stringency specifies a rank order but is mute on relative differences, it is less restrictive. This final point also applies to any phonetic differences between languages that might be more fine-grained than a given theory of phonological features encodes (e.g. coda singleton [n] being slightly longer in one language than in another). Assuming such differences exist, the proposal here, unlike stringent constraints, predicts them to be relevant to gradient weight.

6 Conclusion

This article challenges the often assumed but rarely tested position that syllable weight is exclusively binary in metrics (see especially Jakobson 1933 and Devine & Stephens 1976 for explicit statements of this view). Case studies of four quantitative metres drawn from three language families in every case reveal sensitivity to a continuum of weight within the heavies. Gradient weight in each case characterises an interval scale, in which differences are a matter not just of ranking, but also of relative degree. Furthermore, the scales obtained across traditions are well

correlated, not only with each other, but also with the hierarchies inferred from the cross-linguistic typologies of stress and other weight-sensitive phenomena.

In §4.3 and §5.1, it was argued that the features of the gradient scale need not be stipulated, but emerge directly from the perceptual-phonetic interface via constraints whose degrees of violation are phonetically defined (as in Flemming 2001). A maxent constraint grammar approach in which these scalar/gradient constraints coexist with their categorical counterparts generates the attested typology of (i) complete categorisation, (ii) incomplete categorisation, as in the Kalevala metre, in which the phonology is clearly polarised towards categories (*vis-à-vis* the phonetics), but the phonetic interface continues to leak through within categories, (iii) mixed categorical-gradient systems, as in the Greek hexameter, in which a categorical cut-off is impermeable, but intra-categorial gradience is also observed, and (iv) fully gradient, direct interface systems, of which Kamban's Tamil metre is possibly a case.
